## Problem description

```
example : 2^(n + 1) * m = 2 * 2^n * m := by {  
  -- What now ?  
}
```

We just need to use the theorem that says that  $2^{n+1} = 2 \cdot 2^n$  (pow\_succ).

Or, even better, have the system prove it automatically.

Issues:

- ▶ mathlib has over 100k theorems.
- ▶ There are ways to search but they are very strict.

# Solution

Turn this problem into a machine learning task where:

- ▶ **Input:** the theorem statement (featurized).
- ▶ **Output:** list of premises that appear in the proof.

Design principles:

1. Tight integration with the proof assistant.
2. Easy to use and install.
3. Lightweight and fast.

Data extraction, training, and prediction all happen in Lean.

# Features

`theorem le_of_pred_lt {m n : ℕ} : pred m < n → m ≤ n := ...`

We consider the syntax tree of the elaborated expressions:

- ▶ Names: `T:LE.le T:instLENat T:Nat H:Nat H:LT.lt H:instLTNat ...`
- ▶ Bigrams: `T:LE.le/instLENat T:LE.le/Nat H:LT.lt/Nat ...`
- ▶ Trigrams: `T:LE.le/Nat/instLENat H:LT.lt/Nat/instLTNat ...`

## Relevant premises

The proof is also an expression so, in principle, we could just traverse it and keep track of all the premises found.

However, this results in a large number of simple facts and autogenerated lemmas...

We apply three filters<sup>1</sup>:

- ▶ All (42k): remove premises automatically generated by Lean.
- ▶ Math (40k): remove premises from the core library, e.g. `rf1`.
- ▶ Source (21k): only keep lemmas explicitly written in the proof.

```
match m with
| 0 => le_of_lt
| m + 1 => id
```

---

<sup>1</sup>In brackets: number of theorems with non-empty premise lists after filtering

# Random forest

**Key idea:** many (uncorrelated) decision trees + voting.

Our decision trees:

- ▶ Leaves hold a list of premises and a list of examples.
- ▶ Nodes consist of a simple rule checking if a feature appears.
- ▶ The output is a ranking of premises.

# Random forest

A key difference with the usual approach is that we train it in an *online* fashion, i.e. we update the model one example at a time. It makes it easy to update the model as new theorems are proved.

The steps to add an example  $e$  to a tree are:

1. Follow the binary rules down to a leaf  $L$ .
2. Let  $L = L \cup \{e\}$ . If  $split(L)$ , continue, else stop.
3. Select  $N$  features by successively taking random pairs of examples in  $L$  and picking a feature in their difference set.
4. The new rule  $f$  is the feature maximizing “information gain”.
5. Split  $L$  based on  $f$  into  $L_1$  and  $L_2$  and let  $L = (f, L_1, L_2)$ .

## Evaluation and results

Split training and test sets based on `mathlib` modules:

- ▶ Test (592): Modules that are not dependencies.
- ▶ Training (2436): The rest of the modules.

Assume a theorem  $T$  depends on a set  $P$  of  $n$  premises. We measure the quality of a ranking  $R$  as follows:

$$\text{Cover}(T) := \frac{|P \cap \{R[0], \dots, R[n-1]\}|}{n}$$

We also consider taking  $n + 10$  premises from  $R$  instead of  $n$ .

## Evaluation and results

Average cover for our model with different filters and features:

	n	n+b	n+b+t
All	0.56 (0.67)	<b>0.57</b> (0.67)	0.47 (0.58)
Source	0.28 (0.36)	<b>0.29</b> (0.36)	0.28 (0.36)
Math	0.25 (0.32)	<b>0.26</b> (0.33)	0.16 (0.24)

Observations:

- ▶ More strict filters make the learning task harder.
  - ▶ Fewer data points.
  - ▶ It is “easy” to predict very common premises.
- ▶ Trigrams caused over-fitting.

# The suggest\_premises tactic

It can be invoked in tactic mode, producing suggestions instantly.

The screenshot shows the Lean IDE interface. The left pane displays the source code for `TacticTest.lean`. The code includes imports for `mathlib`, `Mathlib.Algebra.Group.Defs`, `PremiseSelection.Tactic`, and `PremiseSelection.Widget`. It defines a `RightCancelMonoid` structure `M` and a variable `a`. The goal is to prove `b = a * b ↔ a = 1`. The `suggest_premises` tactic is being used in tactic mode, with a tooltip showing the message: "You, yesterday \* feat: you can now cli".

The right pane shows the `Lean Infoview` window. It displays the current tactic state and the results of the `suggest_premises` tactic. The tactic state shows the goal `b = a * b ↔ a = 1` and the variable `a`. The `Premise Selection` window shows the following suggestions:

- `@eq_comm`  `rw [eq_comm] ⊢ b = a * b ↔ a = 1`
- `@mul_left_eq_self`  `apply mul_left_eq_self`
- `@Iff.intro`  `apply Iff.intro ⊢ a * b = b → a = 1`

The window also indicates that 14 items were finished checking.

# Conclusion

The code is publicly available at:

<https://github.com/BartoszPiotrowski/lean-premise-selection>

Things I omitted:

- ▶ We also used  $k$ -NN in a similar way.
- ▶ We experimented with premises from intermediate proof states (we extracted them using LeanInk).

Future work and questions:

- ▶ Re-train on fully ported `mathlib`.
- ▶ Better features exploiting the structure of expressions.
- ▶ Use our ML advisor with automated approaches, e.g., `duper`.
- ▶ Package for `mathlib` users?
